Erosion Potential Method (Gavrilović Method)
Sensitivity Analysis

Abstract

In recent decades, various methods for erosion intensity and sediment production assessment have been developed. The necessity for better model performance has led to the more frequent application of the method sensitivity and uncertainty assessments in order to decrease errors that arise from the model concept and its main assumptions. The analysis presented in this paper refers to the application of the Gavrilović method (Erosion Potential Method), an empirical and semi-quantitative method that can estimate the amount of sediment production and sediment transport as well as the erosion intensity and indicate the areas potentially threatened by erosion. The emphasis in this paper is given upon the method sensitivity analysis that has not previously been conducted for the Gavrilović method. The sensitivity analysis was conducted for fourteen different parameters included in the method, all in relation to different model outputs. Each parameter was perceived and discussed individually in relation to its effect upon the method outputs, and ranked into categories depending on their influence on one or more model outputs. The objective of the analysis was to explore the constraints of the Gavrilović method and the method response to changes deriving from the each individual parameter in an attempt to provide a better understanding of the method, the weight and the contribution of each parameter in the overall method. The parameters that could potentially be used in future research, for method modification and calibration in areas with different catchment characteristics (e.g. climate, geological, etc.) were identified. The most sensitive model parameters resulting from conducted sensitivity analysis for the Gavrilović method are also those considered to be significant in the scientific literature on erosion. The Gavrilović method sensitivity analysis has been done on a case study for the Dubracina catchment area, Croatia.

Keywords: erosion assessment; erosion intensity; input parameters; method sensitivity; sediment production

The need for information on soil erosion (MERRITT et al. 2003), at temporal and spatial scales describing the sediment pattern throughout the catchment and its associated quantities, is increasing due to various demands from stakeholders and decision makers in spatial as well as soil and water conservation planning. In recent decades, many methods for erosion intensity and sediment production assessment have been developed. The necessity for better model performance has led to more frequent application of the method sensitivity and uncertainty assessments in order to decrease errors that arise from the model concept and its main assumptions (MERRITT et al. 2003). According to LOUCKS and VAN BECK (2005), any model credibility relies on the accuracy and reliability of its outputs. There is a difference between the model uncertainty and the sensitivity analysis. While the uncertainty analysis attempts to identify magnitudes and conditions under which the model yields the highest uncertainties as well as the average output uncertainty for a wide variety of modelling conditions (CHAVES & NARING 1991), the sensitivity analysis aims to determine the alteration of the model output as a function of the change in
each one or in a set of input parameters (Loucks & Van Beck 2005; Morgan 2005) and quantitatively evaluates the influence of input parameters to model outcome. Numerous studies (e.g. Jetten et al. 1999, 2003; Tucker & Whipple 2002; Tucker 2004; Van Griensven et al. 2006) applied sensitivity analysis on various erosion models such as MPSIAC (Behnam & Parehkhar 2011), CREAM (Lane & Ferreira 1982), EUROSEM (Veihie & Quinton 2000), WEPP (Nearing et al. 1990), PSEM-2D (Nord & Esteves 2005), USLE (Tattari & Bålund 2001; Liu & Liu 2010), GUEST (Misra & Rose 1996), ANSWERS (De Roo et al. 1989), etc. Furthermore, White and Chauhey (2005) used sensitivity analysis to identify the parameters that most influence predicted flow, sediment and nutrient outcomes for the Soil and Water Assessment Tool (SWAT) model. Lenhart et al. (2002) applied two different approaches to sensitivity analysis on the same model (SWAT). Sensitivity analysis was conducted for the hydrological and soil erosion model LISEM (the Limburg soil erosion model) by De Roo et al. (1992). Mendicino (1999) used sensitivity analysis on different GIS-based methodologies to estimate the Length-Slope factor in order to determine which of these is more reliable for spatial erosion risk assessment.

The analysis in this paper comprises the Gavrilović method sensitivity analysis. The objective of the present research and analysis is to explore the constraints of the Gavrilović method and its response deriving from the change in each individual parameter in an attempt to provide a better understanding of the method, the weight and contribution of each parameter in the overall method output. The analysis in this paper is based on the case study for the Dubracina catchment area, Croatia.

**MATERIAL AND METHODS**

The Gavrilović method (Erosion Potential Method, EPM) is an empirical, semi-quantitative model (Gavrilović 1972). The method was based on erosion field research in the Morava River catchment area in Serbia and encompasses erosion mapping, sediment quantity estimation, and torrent classification. Since 1968, the method has been extensively applied to erosion and torrent-related problems in the Balkan countries. It is currently being applied worldwide, from Switzerland, Croatia, Serbia, Slovenia, Italy, the Republic of Macedonia, Bosnia and Herzegovina, Montenegro, Iran to Chile (e.g. Bemporad et al. 1997; Globevnik et al. 2003; Fanetti & Vezzo 2007; Solaimani et al. 2009; Amiri et al. 2012; Kaymierski et al. 2013; Spalević et al. 2013; Dragićević et al. 2014, etc.). The most often calculated outputs of the method (Table 1) are (i) the total annual volume of detached soil \( W_a \) (Table 1, Eq. (1)), (ii) the erosion coefficient \( Z \) (Table 1, Eq. (3)), and (iii) the actual sediment yield \( G_y \) (Table 1, Eq. (6)).

The Gavrilović method does not explore the physics of erosion processes and as such it is advantageous for areas where minimal data are available or where there is a lack of previous erosion research. As such, the method provides an estimate not only of the amount of sediment production and sediment transport, but also of the resulting erosion intensity.

The analysis in this paper comprises the Gavrilović method sensitivity analysis. The objective of the present research and analysis is to explore the constraints of the Gavrilović method and its response deriving from the change in each individual parameter in an attempt to provide a better understanding of the method, the weight and contribution of each parameter in the overall method output. The analysis in this paper is based on the case study for the Dubracina catchment area, Croatia.

**MATERIAL AND METHODS**

The Gavrilović method (Erosion Potential Method, EPM) is an empirical, semi-quantitative model (Gavrilović 1972). The method was based on erosion field research in the Morava River catchment area in Serbia and encompasses erosion mapping, sediment quantity estimation, and torrent classification. Since 1968, the method has been extensively applied to erosion and torrent-related problems in the Balkan countries. It is currently being applied worldwide, from Switzerland, Croatia, Serbia, Slovenia, Italy, the Republic of Macedonia, Bosnia and Herzegovina, Montenegro, Iran to Chile (e.g. Bemporad et al. 1997; Globevnik et al. 2003; Fanetti & Vezzo 2007; Solaimani et al. 2009; Amiri et al. 2012; Kaymierski et al. 2013; Spalević et al. 2013; Dragićević et al. 2014, etc.). The most often calculated outputs of the method (Table 1) are (i) the total annual volume of detached soil \( W_a \) (Table 1, Eq. (1)), (ii) the erosion coefficient \( Z \) (Table 1, Eq. (3)), and (iii) the actual sediment yield \( G_y \) (Table 1, Eq. (6)).

The Gavrilović method does not explore the physics of erosion processes and as such it is advantageous for areas where minimal data are available or where there is a lack of previous erosion research. As such, the method provides an estimate not only of the amount of sediment production and sediment transport, but also of the resulting erosion intensity.

**Table 1. Equations and description of the parameters for the Gavrilović method (De Vente & Poesen 2005)**

\[
W_a = T \times P_a \times X_a \times \phi \times \sqrt{2 \times F} \quad (1)
\]

\[
T = \frac{T_0}{10} + 0.1 \quad (2)
\]

\[
Z = Y \times X_a \times (\phi + \sqrt{J_p}) \quad (3)
\]

\[
\xi = \frac{O \times z}{(l_p + 10)} \times D_d \quad (4)
\]

\[
D_d = \frac{l_p + l_s}{F} = \frac{L}{F} \quad (5)
\]

\[
G_y = \xi \times W_a \quad (6)
\]

- \( W_a \): total annual volume of detached soil (m³/year)
- \( T \): temperature coefficient (°C)
- \( P_a \): average annual precipitation (mm)
- \( Z \): erosion coefficient (–)
- \( F \): study area (km²)
- \( T_0 \): average annual temperature (°C)
- \( Y \): soil erodibility coefficient (–)
- \( X_a \): soil protection coefficient (–)
- \( \phi \): coefficient of type and extent of erosion (–)
- \( J_p \): average slope of the study area (%)
and indicates areas of potential erosion threats. On the example of the Tartano Basin (Italy), Ballio et al. (2010) conducted sensitivity analysis of the Gavrilović method for only three parameters: (i) soil protection coefficient $X_a$, (ii) soil erodibility coefficient $Y$, and (iii) coefficient of type and extent of erosion $\phi$ with the parameter value deviation of $-25\%$ for $X_a$, $+11\%$ for $Y$, and $+6.2\%$ for $\phi$ in relation to values defined by the base case scenario. The authors noted the differences between the obtained values for model outputs, ranging the values for the Actual sediment yield $G_y$ from $+5$ to $-35\%$, the former being the result of a change in parameter $\phi$ and the later in parameter $X_a$.

Dragičević et al. (2014) analyzed uncertainties in the magnitude and spatial distribution of annual sediment production predictions in the Dubračina catchment, Croatia, where several alternative land cover/use inputs were applied. They used three different land cover/use data sets: a CORINE land cover map, a Spatial Plan, and a Landsat 8 scene, and demonstrated the variations in the Gavrilović method output caused by different land cover/use inputs.

The analysis shown in this paper includes sensitivity analysis of all Gavrilović method parameters in relation to the following erosion model outputs: (i) the degree of annual soil loss ($W_a$), (ii) erosion intensity ($Z$), and (iii) eroded material transported through the river network ($G_y$). The analysis includes the calculation of the dimensionless Sensitivity Index $I$ (Eq. (10)) (Lenhart et al. 2002) for each of the fourteen method parameters in relation to different model outputs. The dependence of model output $y$ on any parameter $x$ can be expressed as the partial derivative $\delta y/\delta x$. The approximation of this derivative is:

\[ I = \frac{y_2 - y_1}{2\Delta x} \]

Further, the calculated index $I$ must be normalized to obtain the sensitivity index $I'$:

\[ I' = \frac{y_2 - y_1}{y_0} \]

standard deviation (see Hamby 1994, 1995; Frey & Patil 2002; Cariboni et al. 2007; Satelli et al. 2008). The sensitivity index for each parameter, using the approach proposed by Lenhart et al. (2002), is calculated such that only the parameter being evaluated is varied by ± 10% while all other parameters remain the same as in the base model variant. Each sensitivity index is then assigned a sensitivity class (Table 2) according to its resulting values for each individual parameter (Table 4) in relation to the output of the model.

The Gavrilović method sensitivity analysis is based on the example of the Dubračina River catchment area, Croatia (Figure 1). This small catchment (43 km² in size) is characterized by its valuable natural and cultivated landscape, biodiversity, cultural and historical heritage as well as high annual rainfall, steep topography, and variable geology, all contributing to its land instability features such as landslides and excessive erosion processes. Although most of its tributaries (Figure 1a) tend to dry out dur-

Figure 1. Dubračina catchment, Croatia: river network distribution and position of the town and meteorological station Crikvenica (a), elevation (b), soil type by category number (c), slope angle in degrees (d), land cover distribution (e), and land cover in percentage (f)
ing the summer period, during the rainy period, considerable flow oscillations are very common. The overall catchment can roughly be divided into an upper karstic part with steep slopes and active sediment movement and a lower Flysch as a less permeable area. The complexity of soil structure in the Dubračina River catchment is evident from soil categories shown in Figure 1e and corresponding Table 3, where each category comprises several soil types whose interrelationship is defined by percentage ratio. The catchment stretches from 0 up to 920 m a.s.l. with steep slopes in its lower and upper part and less steep slopes in the middle part. The land cover description is based on Landsat 8 scene which recognizes six different land cover categories. Among them, medium density vegetation covers the largest area (31%) while bare soil to rare vegetation along with bare rock together covers 47% of the Dubračina catchment area. The complex geological structure, special valley cross section with distinct and steep slopes affected by erosion, local landslides and torrents, are the reason this area has been known for many years as an area of potential hazard.

For the purposes of this analysis, detailed and comprehensive data collection for the Dubračina catchment was conducted using sources from a variety of academic, governmental, and non-governmental institutions (Sušanj et al. 2013). The necessary data can be subdivided into spatially variant input parameters (land use/cover, precipitation, temperature and land cover, soil erodibility, average slope of the study area, coefficient of type and extent of erosion, and mean difference in elevation of the study area) and spatially invariant parameters (study area, perimeter of the watershed, length of the principal waterways, and cumulated length of the principal and the secondary waterways). The spatial distributions of precipitation and temperature, with a resolution of 1000 × 1000 m, were obtained from the Croatian Meteorological and Hydrological Service for the time period of 1961–1990 (past time), as well as the average annual temperatures and the total annual precipitation for the meteorological station Crikvenica (Figure 1a) from 1961 to 2014. Since all other data represent conditions on the catchment in the present time, the same had to be made for the precipitation and temperature with the assumption that the time period 1991–2020 represents the present time. Both the difference in the mean values between the two time periods (1961–1990 and 1991–2014) (Table 4) and trends encompassing the time range from 1961 to 2014 (Figure 2) indicate the increase in values for both parameters. The statistical analysis, t-test with 95% of confidence (two-tailed test), was conducted with a purpose to define if the difference within the mean values between the two time periods, for both temperature and precipitation, is significant. The null hypothesis assumes that the two data sets are likely to have come from distributions with equal population means. For the temperature parameter (P-value \(9.21 \times 10^{-8} < \alpha (0.05)\)), the analysis has confirmed a significant change in temperature mean values for the two time periods, which was not the case with the precipitation (P-value (0.249) > \(\alpha (0.05)\)). Based on the results,

SD – standard deviation

on twenty-four-year changes (data available from 1991 until 2014) in total annual rainfall and average annual temperature for the town of Crikvenica, and on the assumption that the spatial distribution pattern remains the same throughout the catchment for both past and present time series, the spatial distribution maps for these parameters were derived from the present time to correspond in all other input parameters.

Note that both the average annual temperature \( T_0 \) and the average annual precipitation \( P_a \) for the town of Crikvenica were found to increase in the period from 1991 till the present compared to the period 1961–1990 (by 0.9°C and 55.9 mm). The differences in the input data sets for temperature and precipitation are based on these changes.

The soil erodibility coefficient is based on a pedological map of Primorsko-Goranska County on a scale of 1:100 000. The soil protection coefficient is based on the Landsat 8 data with a cell size 30 × 30 m. The land cover data that latter defines soil protection coefficient was obtained using supervised classification on the Landsat data and the ERDAS Imagine 2014 software. Furthermore, LIDAR data were used to generate a digital elevation model with a 2 × 2 m cell size spatial resolution, from which the average slope of the study area map and mean difference in elevation of the study area was derived. The coefficient of type and extent of erosion was based on the Spatial Plan map of known erosion-affected areas (scale 1:25 000). The drainage density map was based on river (primary and secondary) density calculated from the centre point of each map cell taking into account the values of all cells within the square of 1000 × 1000 m. The Map for the main difference in elevation of the watershed is produced in a similar way as the Drainage density map.

**RESULTS**

For the Gavrilović method sensitivity analysis, twenty-nine model variations were derived, and a total of fourteen model parameters were analyzed and varied by ±10% to obtain the values for the Sensitivity index \( I \) for each affected model output (Table 5). The included parameters can be divided into three categories: (A) the parameters that affect all three model outputs \( (W_a, G_a, \text{ and } Z) \), (B) the parameters that affect both \( W_a \) and \( G_a \), and (C) the parameters that only affect \( G_a \).

The parameter with the highest sensitivity for all model outputs is the soil erodibility coefficient \( Y \), followed by the soil protection coefficient \( X_a \). Although overall \( X_a \) is a parameter with a very high sensitivity to the model, its slightly lower value compared to \( W_a \) classifies it as a high-sensitivity model parameter. All B category parameters are considered to be in the very high or high-sensitivity class in addition to the Average annual temperature \( T_0 \). It is well known that temperature and precipitation have a large impact on erosion processes, precipitation more than temperature within the climate area for which the model was primarily developed. As expected, the model sensitivity class for the Average annual temperature \( T_0 \) is lower than the Average annual precipitation \( P_a \) but, when the Average annual temperature \( T_0 \) is transformed into its related form as the Temperature coefficient \( T \), its sensitivity class is upgraded by one class.

The category C parameter with a very high sensitivity is the Sediment delivery ratio \( \xi \), which is a product of all other category C parameters included in the analysis, all of which are in the high model sensitivity class except for the Length of the principal waterway \( l_p \) with medium sensitivity.

**DISCUSSION**

Summarizing the analysis, the authors assigned sensitivity classes for each of the fourteen different parameters included in the method, with the objective of providing a better understanding of the method and the contributions of each parameter to differ-
ent model outputs. The model outputs are mainly based on the multiplication of the model parameters; thus, for example, when varying the Average annual temperature $P_a$, the model outcome Total annual volume of detached soil $W_a$ will vary proportionally. Not all parameters are included in the model through multiplication, e.g., Average slope of the study area $J_a$, Average annual temperature $T_0$, and Drainage density $D_d$. Most of these parameters are categorized as high- or medium-sensitivity, whereas those in the multiplication form are classified as very high-sensitivity parameters.

It is for a discussion if the coefficient of type and extent of erosion $\phi$ should have lower impact upon the method outputs. Although sensitivity of the method output $W_a$ in relation to $\phi$ is medium, its effect on $Z$ and $G_y$ remains classified as high. This parameter, although usefull, is one of the parameters that are not as commonly used as input parameter in other similar methods for erosion sediment assessment. The same can be said for $O$, $z$ and $l_p$, $l_a$ and $L$ representatives of the study area characteristics, that highly affect $G_y$. Ballio et al. (2010) conducted the sensitivity analysis of the Gavrilović method for parameters $\phi$, $Y$, $X_a$ but left out a conclusion about the sensitivity parameter ranking. Nevertheless, they noted significant changes in model output values caused by the change in input parameters, particularly soil protection coefficient $X_a$ which is, according to sensitivity analysis conducted on the example of Dubračina catchment area, a high to very high-sensitivity parameter. Soil erodibility coefficient and soil protection coefficient $X_a$ are considered very high-sensitive parameters with $X_a$ being a high-sensitive parameter in relation to $W_a$ model output. Dragičević et al. (2014) analyzed the effect of using different information sources for land use/cover parameter $X_a$ and noted significant deviation in model output values. Although, their analysis explores the parameter uncertainty in a model, it is also closely related to parameter sensitivity analysis since both analyses take into consideration the deviation in a parameter value, whether intentionally choosing the percentage for which its value will differ or choosing among various data whose deviation is defined by other external factors.

The second thing that should be taken into consideration during model calibration and modification in order to mitigate model errors and uncertainties is whether or not the average annual temperature is given a high enough significance in the model. The question is if the integration of $T_0$ in this way in the method restricts its use only within the areas of similar climate. Both precipitation and temperature are considered to be highly significant by world

scientific literature whereas within the Gavrilović method temperature is mitigated through the temperature coefficient.

Average slope length and gradient of the study area have a great impact upon water erosion, runoff, and downslope sediment transport and as such represent study area topography (KINNEL 2000; BLANCO & LAL 2010; SHI et al. 2012). The impact of this parameter \( I_y \) upon a method outcome is high but according to its calculated values for sensitivity index \( I_x \) falls within parameters with lower high-sensitivity class values. All these parameters could potentially be used in future research where the need for its modification and method calibration presents for research areas with different characteristic (e.g. climate, geological, etc.) than those applied to this day.

VAN GRIENSVEN et al. (2006) indicated the dependence of parameter sensitivity ranking, for higher ranked parameters, on the variable, the location, and case study. They highlighted the need for the sensitivity analysis to be conducted on each new catchment study in order to select a subset of parameters to be used for model calibration or/and uncertainty analysis. Overall, the most sensitive model parameters resulting from the conducted sensitivity analysis for Gavrilović method are also those considered significant in the scientific literature on erosion (e.g. TOY et al. 2002; MORGAN 2005, etc.).

Acknowledgements. The authors thank the University of Rijeka for financially supporting the publication of this paper (Research Project 13.05.1.3.08 – Development of New Methodologies in Water and Soil Management in Karstic, Sensitive and Protected Areas). This research was based on the work conducted within the following projects: Croatian-Japanese Project “Risk identification and Land-use Planning for Disaster Mitigation of Landslides and Floods in Croatia”, “Hydrology of Sensitive Water Resources in Karst” (114-0982709-2549) financed by the Ministry of Science, Education and Sports of the Republic of Croatia and Hydrology of water resources and risk identification of flooding and mudflows in the karst areas (13.05.1.1.03).
